ABSTRACT

The Algebraic Differential Evolution for Permutations (ADEP) has been recently proposed as an effective evolutionary algorithm for permutation-based optimization problems. ADEP is built upon a framework that exploits the rich algebraic structure of the permutations search space. In this paper we further explore the abilities of ADEP by presenting an implementation for the Single Row Facility Layout Problem (SRFLP): a permutation problem with interesting real-world applications ranging from designing the layouts of machines in certain manufacturing systems to optimally arranging rooms in hospitals. An experimental investigation was conducted on a set of commonly adopted benchmarks and different settings ADEP were compared among them and with respect to the other methods in the literature. Interestingly, the experimental results confirm the validity of ADEP by showing its competitiveness with respect to the state-of-the-art results for the SRFLP.

1 INTRODUCTION

Differential Evolution (DE) is a powerful meta-heuristic algorithm originally proposed for continuous optimization problems [32]. Nevertheless, there are also many applications of DE to combinatorial problems. In most of them, DE was adapted to work into discrete spaces by means of transformation techniques that decode a numerical vector (genotype) into a corresponding discrete solution (phenotype) during the evaluation step. See for instance [10, 13, 21].

However, a single discrete solution could be represented by a potentially infinite number of continuous individuals, hence the continuous-to-discrete transformation schemes introduce a one-to-many mapping from the phenotypic to the genotypic space. Thereby, large plateaus are very likely to be introduced in the search landscape.

In order to overcome these issues, we have recently proposed a discrete realization of DE which is based on an algebraic framework for combinatorial optimization based on strong mathematical foundations. The proposed algebraic DE directly works on discrete search spaces by simulating the behavior of its numerical counterpart [32]. In particular, the discrete differential mutation operator is directly defined on the solution space of the discrete problem at hand.

Actually, the algebraic framework, thus the algebraic DE, tackle all the optimization problems whose search space can be represented by means of a finitely generated group. This requirement is met by most of the combinatorial search spaces commonly considered like, for instance, the space of binary strings [26] and that of permutations [6].

In the case of permutations, the algebraic differential mutation has been firstly implemented using a generating set based on the adjacent swap moves [27, 29] and the corresponding Algebraic Differential Evolution for Permutations (ADEP) has been applied to the flowshop scheduling problems [29, 30] and to the linear ordering problem [4, 28] where, respectively, state-of-the-art and competitive results have been obtained. In [5, 7, 8] ADEP has been extended by introducing other generating sets based on exchange, insertion and reversal moves. These new variants of ADEP have been applied to the linear ordering problem with cumulative costs [7] and to the traveling salesman problem [8].

In this paper we further explore the abilities of ADEP as a solver for permutation-based optimization problems by tackling the Single Row Facility Layout Problem (SRFLP). The SRFLP is an NP-hard problem widely studied in the literature [3, 31] where the goal is to find a linear arrangement, i.e., a permutation, of a set of facilities in order to minimize the sum of their pairwise distances in the linear order. The SRFLP has interesting real-world applications ranging from designing the layouts of machines in certain manufacturing systems [17] to arranging rooms in hospitals [31].

An experimental investigation was conducted on a set of commonly adopted benchmarks for the SRFLP. Different settings of ADEP were experimentally compared and the results obtained by the best setting were also compared with the state-of-the-art results from the literature.
The rest of the paper is organized as follows. Section 2 describes the SRFLP by also reporting the most recent works in the literature. Sections 3 recalls the working scheme of the algebraic DE, while Section 4 describes the implementation of ADEP used in this work. Experimental findings are described in Section 5, while Section 6 concludes the paper by also depicting future lines of research.

2 THE SINGLE ROW FACILITY LAYOUT PROBLEM

2.1 Problem definition

The Single Row Facility Layout Problem (SRFLP), also known as one-dimensional space allocation problem [31], aims to find an optimal linear arrangement of a set of rectangular facilities of equal height but different lengths. In particular, the objective is to minimize a weighted sum of the distances between the centers of all pairs of facilities in the linear arrangement.

Formally, a SRFLP instance is given as a set of $n$ facilities $F = \{1, 2, \ldots, n\}$ and any facility $i \in F$ has length $l_i > 0$. Moreover, a transmission cost $c_{ij} \geq 0$ is given for any pair of facilities $i, j \in F$ with $i \neq j$. Also note that the transmission costs are symmetric, i.e., $c_{ij} = c_{ji}$ for all $i, j \in F$. An SRFLP solution is thus a permutation $\pi = (\pi(1), \pi(2), \ldots, \pi(n))$ of the facilities in $F$, whose cost $C(\pi)$ is

$$C(\pi) = \sum_{q=1}^{n-1} \sum_{r=1}^{n} c_{\pi(q), \pi(r)} d(\pi(q), \pi(r)),$$

where $d(\pi(q), \pi(r))$ is the distance between the centers of the facilities $\pi(q)$ and $\pi(r)$, which is calculated as

$$d(\pi(q), \pi(r)) = \frac{l_{\pi(q)}}{2} + \frac{l_{\pi(r)}}{2} + \sum_{s=q+1}^{r-1} l_{\pi(s)}.$$

Therefore, the goal is to find a permutation $\pi^*$ of the facilities in $F$ that minimizes the objective function given in (1). Formally, $\pi^*$ is a permutation from the set $S_n$ of all the permutations of $n$ items, such that

$$\pi^* = \arg\min_{\pi \in S_n} C(\pi). \quad (3)$$

The SRFLP has interesting real-world applications such as: arranging rooms in hospitals or offices in buildings [31], designing layouts of machines in flexible manufacturing systems [17], assigning information to disk cylinders in computer storage [18], or warehouse design [23].

2.2 Related Work

SRFLP has been proven to be an NP-Hard problem in [11]. For this reason, exact approaches – like, for instance, branch and bound and integer linear programming [16] – allow to solve only relatively small instances of the problem.

Therefore, many (meta)heuristic methods for the SRFLP have been proposed in the literature. Two genetic algorithms have been presented in [15] and [1]. A particle swarm optimization algorithm (PSO) for the SRFLP has been introduced in [25], while another swarm intelligence scheme equipped with a local exchange heuristic has been devised in [35]. Local search approaches are the tabu search and variable neighborhood search proposed in, respectively, [33] and [22]. Other interesting meta-heuristics are GENALGO, a genetic algorithm introduced in [18], and SS-P2, a scatter search approach reported in [19]. Finally, a greedy adaptive search for the SRFLP has been proposed in [14, 24], which also use a path relinking operator in the context of the SRFLP.

One of the most recent and prominent algorithms for the SRFLP is the population-based improvement heuristic with local search [3], which is later referred to as PBHH. This algorithm is among the state-of-the-art methods together with the local search based approaches, i.e.: the variable neighborhood search [22], the tabu search [33], and the location exchange heuristic [35].

3 ALGEBRAIC DIFFERENTIAL EVOLUTION

3.1 Abstract definition

As described in [7, 29, 34], the Algebraic Differential Evolution (ADE) simulates the behaviour of the classical DE in a discrete search space representable by a finitely generated group. The population $\{x_1, \ldots, x_N\}$ of $N$ candidate solutions is iteratively evolved by the three operators of differential mutation, crossover and selection. As widely recognized in the literature [32], the key operator of DE is the differential mutation (DM), therefore hereinafter we focus on DM that, in its most common variant, called rand/1, generates a mutant $\mathbf{v}$ according to

$$\mathbf{v} \leftarrow x_{r_0} \oplus F \odot (x_{r_1} \odot x_{r_2}),$$

where $x_{r_0}, x_{r_1}, x_{r_2}$ are three randomly selected population individuals, and $F \in \{0, 1\}$ is the scale factor parameter.

In numerical DE, the operators $\oplus, \odot, \ominus$ are the usual vector operations of $\mathbb{R}^n$, while, in ADE, their definitions are formally derived using the underlying algebraic structure of the search space [9].

The triple $(X, \circ, G)$ is a finitely generated group representing a combinatorial search space when:

- $X$ is the discrete set of solutions in the space;
- $\circ$ is a binary operation on $X$ satisfying the group properties, i.e., closure, associativity, existence of a neutral element (or identity $e$), and invertibility ($x^{-1}$); and
- $G \subseteq X$ is a finite generating set of the group, i.e., any $x \in X$ has a (not necessarily unique) minimal-length decomposition $(g_1, \ldots, g_l)$, with $g_i \in G$ for all $i \in \{1, \ldots, l\}$, and whose evaluation is $x$, i.e., $x = g_1 \circ \cdots \circ g_l$.

For the sake of clarity, the length of a minimal decomposition of $x$ is denoted by $|x|$.

Using $(X, \circ, G)$ we can provide the formal definitions of the operators $\oplus, \odot, \ominus$. Let $x, y \in X$ and $(g_1, \ldots, g_k, x_{[x]})$ be a minimal decomposition of $x$, then

$$x \oplus y := x \circ y,$$

$$x \odot y := y^{-1} \circ x,$$

$$F \odot x := g_1 \circ \cdots \circ g_k,\text{ with } k = |F \cdot [x]| \text{ and } F \in \{0, 1\}. \quad (7)$$

The algebraic structure on the search space naturally defines neighborhood relations among the solutions. Indeed, it induces a colored digraph whose vertices are the solutions in $X$ and two generic solutions $x, y \in X$ are linked by an arc with color $g \in G$ if and only if $y = x \circ g$. Therefore, a simple one-step move can be directly encoded by a generator, while a composite move can be synthesized as the evaluation of a sequence of generators (a path on the graph). In analogy with $\mathbb{R}^n$, the elements of $X$ can
be interpreted both as solutions (vertices on the graph) and as displacements between solutions (colored paths on the graph). As detailed in [29], this provides a rational interpretation to the discrete DM of definition (4). The key idea is that the difference $x \odot y$ is the evaluation of the generators in a shortest path from $y$ to $x$.

Clearly, $\odot$ and $\oplus$ do not depend on the generating set, thus they are uniquely defined. Conversely, $\odot$ relies on the chosen generating set and, also fixing it, a minimal decomposition is not unique in general. Therefore, $\odot$ is implemented as a stochastic operator, thus requiring a randomized decomposition algorithm for the finitely generated group at hand.

### 3.2 ADE for Permutations

The Algebraic Differential Evolution for Permutations (ADEP) [29] is an implementation of ADE for the search space of permutations. In fact, the permutations of $[n] = \{1, \ldots, n\}$ can be composed by the operator $\odot$ and form the so-called Symmetric group $S_n$. Different choices for the generating set are possible and, more interestingly, each generating set can be interpreted as a class of moves between permutations. In this work we consider the following three generating sets:

- $\text{ASW}_n$, which is based on adjacent swap moves and it is formally defined as
  \begin{equation}
  \text{ASW}_n = \{\sigma_i : 1 \leq i < n\},
  \end{equation}
  where $\sigma_i$ is the identity permutation with the items $i$ and $i+1$ exchanged. For example, let $\pi = (3, 5, 2, 4, 1)$, then $\pi \odot \sigma_3 = (3, 5, 2, 4, 1) \odot (1, 2, 4, 3, 5) = (3, 5, 4, 2, 1)$.

- $\text{EXC}_n$, which is based on exchange moves and it is formally defined as
  \begin{equation}
  \text{EXC}_n = \{e_{ij} : 1 \leq i < j \leq n\},
  \end{equation}
  where $e_{ij}$ is the identity permutation with the items $i$ and $j$ exchanged. For example, let $\pi = (3, 5, 2, 4, 1)$, then $\pi \odot e_{2, 5} = (3, 5, 2, 4, 1) \odot (1, 3, 5, 4, 2) = (3, 1, 2, 4, 5)$.

- $\text{INS}_n$, which is based on insertion moves and it is formally defined as
  \begin{equation}
  \text{INS}_n = \{u_{ij} : 1 \leq i \leq j \leq n\},
  \end{equation}
  where $u_{ij}$ is the identity permutation where the item $i$ is shifted to position $j$. For example, let $\pi = (3, 5, 2, 4, 1)$, thus $\pi \odot u_{i, 5} = (3, 5, 2, 4, 1) \odot (1, 2, 4, 5, 3) = (3, 5, 4, 1, 2)$.

A minimal decomposition of a permutation $\pi \in S_n$ can be obtained by ordering the items in $\pi$ using a sorting algorithm that only consider moves from the chosen set, i.e., adjacent swaps for $\text{ASW}$, generic exchanges for $\text{EXC}$, and insertions for $\text{INS}$.

Optimal randomized decomposers for $\text{ASW}$, $\text{EXC}$, and $\text{INS}$ have been implemented by means of generalized and randomized variants of, respectively, the bubble-sort, selection-sort, and insertion-sort algorithms [5, 7, 29]. They have been called $\text{RandBS}$, $\text{RandSS}$, $\text{RandIS}$ and exploit different combinatorial properties of the permutations.

Since (the ordered permutation) $\epsilon$ is the only permutation with 0 inversions [29], $\text{RandBS}$ iteratively decreases the number of inversions by swapping two randomly selected adjacent items $\pi_i$ and $\pi_{i+1}$ which form an inversion of $\pi$, i.e., $\pi_i > \pi_{i+1}$. The time complexity of $\text{RandBS}$ is $\Theta(n^3)$.

$\text{RandSS}$ exploits the fact that $e$ is the only permutation with $n$ cycles (of length 1) in its cycles representation, thus it iteratively increases the number of cycles of $\pi$ by randomly breaking a randomly selected cycle. In fact, it turns out that any cycle can be split in two shorter cycles by exchanging any pair of items in the original cycle. The amortized time complexity of $\text{RandSS}$ is $\Theta(n)$.

$\text{RandIS}$ considers that $e$ is the only permutation with a (unique) longest increasing subsequence (LIS) of length $n$, thus it iteratively extends the LIS length of $\pi$ by shifting a suitable item in a suitable position. The time complexity of $\text{RandIS}$ is $\Theta(n^2)$.

For further implementation details, proofs of correctness and complexity we refer the interested reader to [5, 7, 29].

### 4 ADEP for the SRFLP

In this work we present an ADEP implementation purposely defined for the SRFLP. Its pseudo-code is outlined in Algorithm 1.

**Algorithm 1** ADEP scheme for the SRFLP

```plaintext
Randomly initialize the population $\{\pi_1, \ldots, \pi_N\}$
for gen ← 1 to MaxGen do
  for i ← 1 to N do
    $v_i ← \text{DifferentialMutation}(i, \{\pi_1, \ldots, \pi_N\}, F)$;
    $v_i ← \text{Crossover}(\pi_i, v_i)$;
    Evaluate $f(v_i)$
  end for
  Select the population for the next iteration;
  if restart criterion is satisfied then
    Reinitialize the population;
    Apply local search to the best individual $\pi_{best}$;
  end if
end for
Apply local search to the best individual $\pi_{best}$;
```

ADEP directly evolves a population $\{\pi_1, \ldots, \pi_N\}$ of $N$ permutations. For every population individual $\pi_i$, the differential mutation operator builds a mutant $v_i$ by using the algebraic operators introduced in Section 3. Two different mutation scheme have been considered: the explorative rand/1 and the exploitative best/1. They are formally defined in the following two equations:

\begin{align}
  v_i & ← \pi_{\pi_i} \odot F \odot (\pi_{\pi_1} \odot \pi_{\pi_2}), \\
  v_i & ← \pi_{\pi_{best}} \odot F \odot (\pi_{\pi_1} \odot \pi_{\pi_2}),
\end{align}

where $\pi_{\pi_{\pi_i}}, \pi_{\pi_1}, \pi_{\pi_2}$ are three population individuals different from each other and with respect to $\pi_i$, while $\pi_{\pi_{best}}$ is the best individual so far in the population. Moreover, $F \in [0, 1]$ is the scale factor parameter of ADEP which, in this work, is self-adapted during the evolution by means of the popular jDE scheme [12].

The mutant $v_i$ undergoes crossover together with the original population individual $\pi_i$ in order to produce the trial solution $v_i$. Two selection operators are used in ADEP: $\text{ItoI}$ and $\text{Crowd}$. The $\text{ItoI}$ operator replaces $\pi_i$ in the ADEP population with $v_i$ if the latter is fitter than the former, while, in the $\text{Crowd}$ operator, $v_i$ competes with the closest individual in the current ADEP population. Clearly, the fitness $f$ considered in this work is the SRFLP objective function depicted in equation (1).
After some preliminary experiments, five alternative crossover operators for the permutations space have been selected: the three order-based operators O, O2 and OB, the partially mapped crossover PMX and the maximal preservative MP. These are among the most used crossovers for permutation problems and their descriptions can be found, for instance, in [20].

Since the search space is finite, ADEP executions may converge quicker than its numerical counterpart, therefore a soft restart procedure was introduced. The restart is executed when the best individual so far \( \pi_{\text{best}} \) was not improved during the last \( T \) generations. \( T \) is set to 150 after some preliminary experiments. The soft restart consists in: (i) optionally performing a local search starting from \( \pi_{\text{best}} \) and (ii) randomly reinitialize all the other individuals. In this way, the best individual is always maintained in the population, thus guaranteeing an elitist behaviour of ADEP.

The local search is performed by iteratively replacing the incumbent solution with its best neighbor if and only if the latter is fitter than the former (best style local search). The neighborhood based on insertion moves has been adopted since it is considered to be the most effective neighborhood for the SRFLP [24].

## 5 Experiments

In order to evaluate the performance of ADEP in the SRFLP, we have conducted an experimental analysis using the dept instances, introduced in [2], and the sko instances based on the quadratic assignment problem. Both groups of instances are commonly used in the literature as benchmark [3].

The experiments are organized as follows. We have initially performed a tuning phase in order to find the best combination of the ADEP parameters. We have then analysed the impact of equipping the best ADEP configurations with a local search. We have compared the results of ADEP with the state-of-the-art results from the literature. Finally, we have also studied the convergence of the algorithm.

### 5.1 Experimental tuning of ADEP

The ADEP algorithm has six parameters to be set: the generating set \( G \), the mutation operator \( M \), the crossover operator \( C \), the type of selection \( S \), the population size \( N \), and the number of generations \( \text{MaxGen} \). We decided to choose the values of the last two parameters as \( N = 100 \) and \( \text{MaxGen} = 10000 \), while for the other ones we decided to perform a fully factorial tuning phase on the sko instances.

The parameters to be set have the following possible values:

- \( G \in \{ \text{ASW}, \text{EXC}, \text{INS} \} \)
- \( M \in \{ \text{rand/1}, \text{best/1} \} \)
- \( C \in \{ O, O2, \text{OB}, \text{MP}, \text{PMX} \} \)
- \( S \in \{ 1\text{to}1, \text{Crowd} \} \)

Hence the total number of configurations is 60.

For each configuration, the average fitness values over 10 runs per instance have been recorded. We have then computed the average rank for each setting and in Table 1, the top 10 settings are reported.

The best configuration found is \( C_1 = (\text{EXC}, \text{rand/1}, \text{OB}, \text{Crowd}) \) whose average rank value is 2.69.

<table>
<thead>

<td>13.06</td>
</tr>
</tbody>
</table>

Table 1: Configurations ranks

Because of these results, we decided to perform a deeper experimental study between the best configuration \( C_1 \) and the second best \( C_2 = (\text{EXC}, \text{best/1}, \text{OB}, \text{Crowd}) \), which only differs from \( C_1 \) for the value of \( M \). Moreover, we have also analyzed the effect of the local search, comparing these configurations with and without the local search.

### 5.2 Analysis of the local search

The aim of this experimental comparison is to check if the use of the local search (performed when the population is restarted and at the end of the evolution) gives significant improvements on the algorithm performances. Therefore, the two best ADEP configurations

\[
C_1 = (\text{EXC, rand/1, OB, Crowd})
\]

and

\[
C_2 = (\text{EXC, best/1, OB, Crowd})
\]

were compared both with and without considering local search (LS). For this test, ADEP has been executed 10 times for each configuration. The results are provided in Table 2, where we reported the minimum and the average of the fitness function. The results in bold are the best objective functions obtained on a specific instance.

The configuration \( C_2 \) obtained the best results in the 30% of the dept instances, and in the 10% of the sko instances. The configuration \( C_1 \) never reached the best results but in the average case it is better than \( C_2 \) in the 45% of dept instances and 50% of sko ones. The configuration \( C_2 + \text{LS} \) never reached the best results in terms of minimum and average fitness values if compared to the other configurations. It is likely that ADEP with \( M = \text{best/1} \) and the local search easily get stuck in a local minimum.

The configurations \( C_1 + \text{LS} \) produced the best results in terms of the minimum and the average fitness values. It reached the best solution in the 70% of the dept instances and the 90% on the sko instances. Also, in average it is the best configuration, precisely, in the 55% and 50% of the dept and sko instances.

We also performed three Wilcoxon signed-rank tests, among \( C_1 + \text{LS} \) and the three other configurations \( C_2, C_1, \) and \( C_2 + \text{LS} \), whose p-values are, respectively, \( 0.56 \times 10^{-3}, 1.32 \times 10^{-5}, 3.22 \times 10^{-5} \). This means that the configuration \( C_1 + \text{LS} \) is significantly the best ADEP setting.
We have also studied the impact of using or not the local search in very small differences on the sko ones. In fact, ADEP reached the same minima found by PBII in the 55% of the case and its worst result was only 0.003%.

Statistical test reveals that there are no significant differences between the two algorithms on the dept instances, while there are very small differences on the sko ones.

Anyway, as a conclusion, it is possible to state that ADEP, a general purpose solver for permutation problems, can achieve results which are extremely close to the state-of-the-art SRFLP results obtained by algorithms which have been purposely designed for the problem at hand.

### 5.4 Convergence analysis

We have also studied the impact of using or not the local search in terms of the convergence curve on the best ADEP configuration, i.e. $C_1 = (\text{EXC, rand}/1, \text{OB, Crowd})$.

In Figure 1a we present the most representative convergence graph obtained on the dept instances. It is possible to notice that $C_1$ with local search has a smoother descent with respect to the plain $C_1$. In fact, the latter search gets stuck in a local minimum after a few generations; it gets out from there at generation 5000 and then falls in another local minimum at generation 7000. Conversely, $C_1$+LS slowly converges to its final result at generation 7000, which is lower than the result obtained by $C_1$.

We can observe an analogous situation in Figure 1b, where the most representative behaviour on the sko instances is reported.

In fact, as in the dept instances, $C_1$ without local search quickly reaches the final fitness value (found after 2000 generations). On the other hand, $C_1$ with local search has a slower convergence: initially produces worse results than $C_1$, but then it reaches better and better results and converges after 8000 generations.

### 6 CONCLUSION AND FUTURE WORK

In this paper we have presented an Algebraic Differential Evolution (ADEP) algorithm for the Single Row Facility Layout Problem. ADEP is based on the recently introduced algebraic framework for discrete evolutionary algorithms [29, 34] and, in this work, it has been adapted and enhanced for the problem at hand by implementing different crossovers, algebraic mutations, selection operators, a local search method, and a restart procedure. ADEP parameters have been tuned and the best configuration has been compared with the state-of-the-art algorithm PBII, showing that its results are comparable with its competitor.

As a future line of research, we would like to enrich ADEP with other generating sets for the algebraic differential mutation or with other algorithmic components, such as some mechanism to enhance the population diversity, in order to improve its effectiveness.

We are also interested in trying to use ADEP with other similar permutation based or discrete optimization problems, like the Double Row Layout Problem.
